EDDIES AND SPECIATION IN THE CALIFORNIA CURRENT

ABSTRACT
Northern anchovy, Pacific sardine, and Pacific hake have population discontinuities in the vicinity of Punta Eugenia, Baja California. The same latitude has been described as a provincial boundary for several taxa, including coastal fishes, brachyurans, bryozoans, and molluscs. The distribution of wind stress over the surface waters of the California Current region has a persistent feature in the same area: the coastal impingement of a zone of surface water convergence, which elsewhere is parallel to the coast of the Californias and several hundred kilometers offshore. Semipermanent cyclonic eddies are evident north and south of Punta Eugenia, and it has been suggested that they play a role in the recruitment of pelagic larvae to the adult populations in these areas.

Limited communication between the eddies suggests a speciation mechanism that would be most effective on populations that time their spawning to coincide with strong eddy formation. One may also expect geminate species north and south of Punta Eugenia and few short-range endemics with long dispersal strategies along the coast of northern Baja California between the eddies.

INTRODUCTION
Several coastal pelagic fish species display a population break in the vicinity of Punta Eugenia, Baja California. Distinct discontinuities in morphometric measurements, meristic counts, and proportion of selected protein polymorphs suggested restricted gene flow between populations north and south of approximately 28° N for Engraulis mordax, the northern anchovy (Hubbs 1925; McHugh 1951; Vrooman et al. in press), for Sardinops caerulea, the Pacific sardine (Clark 1947; McHugh 1950; Marr 1957, 1960; Sprague and Vrooman 1962; Vrooman 1964), and for Merluccius productus, the Pacific hake (Vrooman and Paloma 1977). Vrooman and Paloma (1977) referred to the southern population of M. productus as “dwarf hake” and suggested that it differs from M. productus and the more southern M. angustimus at the species level. The southern populations of all three fishes (Engraulis mordax, Sardinops caerulea, and Merluccius productus) show similarities in some of the ways they differ from the northern population: growth is reduced after the first year resulting in smaller maximum adult size, maturity occurs at an earlier age, and the life span is shorter; the southern forms have proportionally longer heads, longer snouts, and larger eyes.

The latitude of Punta Eugenia has been described as a provincial boundary for a wide variety of taxa including coastal fishes (Hubbs 1960), brachyurans (Garth 1960), bryozoans (Soule 1960), and molluscs (Hall 1964; Valentine 1966). These authors refer to a variously named warm-temperature fauna between Point Conception and Punta Eugenia and a distinct fauna of uncertain origin from Punta Eugenia south to Cabo San Lucas. Hubbs (1960) tentatively placed this region in the Panamic province but noted the “reduced tropical fauna,” “high endemism,” and “insular characteristics” of the biota.

Superimposed on the distributions of coastal animals are the distributions of invertebrate species as-
associated with oceanic water masses. The distribution of oceanic euphausiids and copepods, indicators of subarctic, equatorial, and central waters, have a common terminus at Punta Eugenia (Brinton 1962, 1967, 1973; Fleischer 1964, 1967). The junction of these distributions appears to move northward or southward in concert with temperature anomalies as described in CalCOFI Atlas Number 1 (Anonymous 1963) and by Wyllie and Lynn (1971), although shallow-water forms show a much clearer response than do deeper forms (Brinton 1960).

HYDROGRAPHY

The general hydrography off the coast of the Californias is determined by the California Current and is related to the anticyclonic circulation of the central North Pacific; however, significant features can be associated with local wind patterns and topography (Sverdrup et al. 1942; Smith 1968). Long-term monthly mean distributions of wind stress show alongshore flow throughout the year, weakest in the winter and strongest in the summer (Nelson 1977). Resolved on a 1° grid, however, net Ekman transport, proportional to and at right angles to the wind stress, shows considerable spatial variability. In general, an area of divergence parallels the coast, bounded by a zone of convergence 200-300 km from the coastline. The position of change from offshore divergence of surface water to convergence corresponds with the position of maximum wind stress, which intensifies, winter to summer, as the gradient between the semipermanent high pressure cell over the eastern Pacific Ocean and the low pressure cell over the southwest United States increases. The zone of convergence impinges the coasts at Punta Eugenia; this feature persists throughout the year and may preclude any poleward movement of water near the coast (Nelson 1977).

Surface current patterns, which describe cyclonic eddies in the Los Angeles Bight and southwest of Punta Eugenia, confirm Nelson's prediction (Bakun and Nelson 1977). Surface flow of the California Current appears to be diverted offshore at Point Conception and again at Punta Eugenia, while semipermanent eddies are apparent south of these headlands (Reid et al. 1958). Owen's (1980) description of baroclinic eddies and their persistence is in accord with this description.

DISCUSSION

The above-mentioned taxa have planktonic larval stages. The coastal eddies may play a role in recruitment to coastal adult populations by entraining a fraction of the larvae, thus offsetting to some extent dispersion to the southwest via the California Current. Johnson (1960) has suggested such a mechanism for maintaining populations of Panulirus interruptus, the spiny lobster, in the Southern California Bight and southwest of Punta Eugenia. Boehlert (1977) recognized the possible importance of the Southern California Eddy to the recruitment of Sebastes spp., rockfishes. Early ichthyoplankton studies off the coast of the Californias found relatively few sardine eggs and larvae off northern Baja California and characterized these waters as a "marine desert" bounded by "rich" waters to the north and south (Anonymous 1952).

If the eddies are important to the process of recruitment, then the limited communication between them suggests a restricted gene flow between populations in the Southern California Bight and those south of Punta Eugenia. This postulated mechanism for speciation lends itself to several predictions:

1. Genetic differentiation between populations, within a species, should be greatest for those forms that time their spawning to coincide with...
strong eddy formation as opposed to those forms that may time their spawning in response to other cycles (e.g. primary productivity).

2. There should be evidence of geminate species north and south of Punta Eugenia: e.g. Labidocera trispinosa and L. johnsoni (Fleminger 1975).

3. On the coast of northern Baja California, between the eddies, there should be a low proportion of dispersal types among sessile populations. A pelagic larval phase would imply dependence on long-range dispersal from the north; instead there should be selection for short pelagic phases or none at all.

4. The latitude of the hydrographic barrier may vary and be obscured by the convergence of oceanic water masses in the same general area which appears to be most pronounced in the upper layers.
