NECTOCARMEN ANTONIOI, A NEW PRAYINAE, CALYCOPHORAE, SIPHONOPHORA FROM CALIFORNIA

Angeles Alvarinoa

Abstract.—Nectocarmen antonioi n. gen., n. sp. was found 13 April 1981 at 33°36.7'N, 118°18.4'W, off California, at a depth of less than 70 m. The siphonophore was complete, with nectophores, gastrozooids, tentacles, palpons, tentilla, bracts, and gonophores. It differs from other genera (Rosacea, Nectodroma or Praya, Prayoides, Lilyopsis, Desmophyes, Stephanophyes) in the subfamily Prayinae in the characteristics of its nectophores, bracts, and gonophores, but constitutes a morphological link among them.

Nectocarmen, new genus

Diagnosis.—A member of the subfamily Prayinae, which includes the genera Rosacea (2 species), Nectodroma or Praya (2 species), Lilyopsis (2 species), Prayoides, Desmophyes, and Stephanophyes (1 species each). The principal characteristics of these genera and of Nectocarmen are given in Table 1.

Type-species.—Nectocarmen antonioi, new species.

Etymology.—Necto ("swimming," Greek) + Carmen, my mother’s name (Latin for poetry, song, and garden).

Nectocarmen antonioi, new species

Figs. 1–5

Material.—Off California, San Pedro Channel, 33°36.7'N, 118°18.4'W, R/V David Starr Jordan sta 88.3 33, cruise 8104, 13 April 1981, vertical tow from about 70 m to surface: Holotype, complete colony, USNM 60895; paratype, eudoxids, USNM 60896.

Etymology.—Named for my father, Antonio.

Description.—The subfamily Prayinae of the suborder Calycophorae are large prayids with pulsating nectophores and a heavy stem. The bracts are composed of a large amount of mesoglea, which aids the flotation of the whole animal. Prayids lack the apical gas-filled float of the Physonectidae, and are propelled by the nectophores at the upper part of the stem, which also supports the large bracts, gastrozooids, palpons, tentacles, tentilla, and gonophores.

The holotype is based on a polygastric specimen with a pair of small nectophores at the top of the stem, and well-developed eudoxids hanging from the stem, along with bracts, gastrozooids, tentacles, palpons, tentilla, gonophores, and free cor- midia. The details of the siphonophore observed have been carefully reproduced, and the whole animal represented in detail in Fig. 1. Drawings give a more reliable representation of specimens than photographs.

Polygastric phase: In the polygastric phase, Nectocarmen antonioi exhibits 2 transparent kidney-shaped cylindrical nectophores, one slightly larger than the...

Fig. 1. *Nectocarum antoniae*, complete specimen, about 200 mm long.
other, with a large nectosac reaching nearly to the top of the nectophore. The
nectophores are 3-4 mm long and about 2.5 mm wide. The hydroecium is only
1/3 the width of the nectophore, and does not run its entire length; it forms a deep
groove, with rounded lobes (superior and inferior) closing the entrance, and this
whole structure is covered by the flaps of the nectophore walls.

The pair of nectophores are bound together by the hydroecium, embracing
each other by this structure (Fig. 2).

The nectosac is large, similar to that of Stephanophyes superba Chun, 1885
(1891) but with differences in the hydroecium, somatocyst, and radial canals. The
pallial canal extends slightly up the nectosac, forming the radial canals. The
anterior and posterior radial canals are straight, and the lateral canals bend up-
ward to a position close to the top of the nectosac, then turn straight down to
the ring or circular canal. The velar end of the nectosac, the ostium, is large,
extending upward at the dorsal side. No ring of minute pigment flecks or tubercles
is observed on the ostium.

The somatocyst is pear-shaped, and lies vertically in the mesoglea, extending
slightly above the top of the nectosac.

Gastrozooids retain the larval tentacle, modified to form a series of tentilla.
The base of the gastrozooids is enlarged into the nematocyst-producing area, the
basigaster.

Palpons of reduced gastrozooids, with simple tentacles or palpacles, serve as
feelers or testers.

The tentilla, with the subterminal battery of nematocysts, are spirally twisted
filaments, with cnidobands (sabre-shaped nematocysts) forming the chief part of
the stinging organs.

Gastrozooids, tentacles, palporns and tentilla lie under the bracts, and are shown
in Fig. 1, and in detail in Fig. 3.

Fig. 2. Pair of nectophores of Nectocamn antonoi (3-4 mm long): A, Small nectophore; B,
Large nectophore; C, Dorsal view of either nectophore. Hydroecium, nectosac, radial and circular
canals, and somatocyst can easily be observed.
Eudoxid phase: The eudoxid phase has no asexual nectophore.

The bracts, which reach a maximum length of 10–12 mm, are oval, kidney-shaped, laterally flattened masses of mesoglea, the inferior part of which is concave and the upper part convex. They are divided into 2 lobes, with a third lobe on the concave distal side forming part of the hydroecial cavity of the bract. Unlike Desmophyes, no central organ (pear-shaped vesicle) is present at the junction of the main bracteal canals.

The bracts contain 4 large canals. The dorsal bracteal canal, which is slightly curved, ends in an ampullar dilatation, as does the nearly straight ventral bracteal canal; left and right hydroecial canals also end in ampullar dilations. The right
Fig. 4. Bracts of *Nectocarmen antonii* (10–12 mm longest axis): A, Lateral right view of two bracts; B, Lateral left view of two bracts.

The bracts, with gastrozooids, tentacles, palpons, tentilla and gonophores, may detach from the stem and swim freely in the ocean.

The sexual gonophores are large and hemispherical in shape, laterally flattened, retaining the medusoid characteristics, but without marginal tentacles. Female and male gonads occupy the mouthless manubrium. The gonophores pulsate intermittently, and are capable of propelling the cormidia in the water.

The gonophores are budded at the stem, below the base of the gastrozooids. They are, as explained, large bells, laterally compressed, with 4 straight radial canals ending at the ring canal. The bells hang from the bract by the pedicular canal, and the four radial canals run from the pedicel to the circular canal. Near the top of the umbrella, the pedicel has trifid branches embedded in the mesoglea, as is seen in *Nectodroma (Praya) reticulata* (Bigelow, 1931). The large, pear-shaped vesicles inside are the female gonads, containing numerous small ova. Male gonads are small, pointed, sausage-shaped vesicles (Fig. 5).

Male and female eudoxids may be found on the same stem.

It is probable that each cormidium includes either male or female gonophores, providing a sexual separation when male cormidia and female cormidia swim...
freely in the ocean. Some of the cormidia were detached, but obviously belonged to the same whole animal.

The nectophores, bracts, and gonophores are transparent; gastrozooids, palpons, and tentacles range in color from bright reddish to faded pink or rose.

The nectophores function in propulsion; the bracts are composed of enlarged masses of mesoglea and act as protection for gastrozooids and gonozoids or gonophores, as well as contributing to the buoyancy of the animal. The stem contracts and expands, and the gonophores also perform active pulsations, contributing to the propulsion of the siphonophores; by spreading the stem into loops they also amplify the potential field of the tentacles and the fishing predatory capacity of the siphonophore.

Discussion.—The principal differential characteristics of the genera in the subfamily Prayinae are presented in Table 1, together with those for Nectocarren n. gen.

The general shape of the nectophores is similar to that of the other genera in the subfamily, especially Rosacea Bigelow, 1911, and Desmophyes Haeckel, 1888, also described by Kawamura (1915). However, the hydroecium is smaller than that of Rosacea, or Desmophyes, and similar to that of Stephanophyes. The nectosac is large, as in Stephanophyes and Lilyopsis (Alvarino 1981; Chun 1885, 1891), but the radial canals do not display the meandering pattern observed in Stephanophyes and Lilyopsis. The somatocyst of Nectocarren is different from that of other Prayinae genera, including Prayoides intermedia Leloup, 1934.
The bracts resemble in general outline those of *Nectodroma* (*Praya*), but differ in the detail of the shape and pattern of the canals, as can be observed by comparing present illustrations with those by Alvariiño (1981), Bigelow (1911), and Totton and Bargmann (1965). Bracts in *Nectocarmen antonoi* do not have the vesicular organ of *Desmophyes*.

The eudoxids of the new siphonophore do not have the large asexual eudoxid nectophore that is found in *Lilyopsis, Desmophyes*, and *Stephanophyes*. The gonophores are similar to those of *Nectodroma* (*Praya*); however, sexual nectophores are pear-shaped in *Nectodroma*, and hemispherical in *Nectocarmen*. Both *Nectodroma* (*Praya*) and *Nectocarmen* present the trifid branched pedicular canal, but the gonads of the former include 4–6 large ova (Bigelow 1931), while in the latter the ova are small and numerous. In *Nectocarmen* the four radial canals of the gonophore converge at the pedicel, and run straight to the circular canal, characteristics different from the other genera in the subfamily, though similar to *Nectodroma* (*Praya*). No tubercles or pigmented spots appear on the margin of the gonophoral umbrella, whereas in the other species of the subfamily those structures are present.

Species of the following *Prayinae* have been observed in California waters (Alvariiño 1967, 1971): *Nectodroma dubia* (Quoy and Gaimard, 1833), *N. reticulata* (Bigelow, 1911), *Rosacea plicata* Bigelow, 1911. Bigelow and Leslie (1930) reported *N. reticulata* from Monterey, but Totton and Bargmann (1965) indicate it was probably *N. dubia*.

There is a peculiar phenomenon common to Siphonophorae and Medusae, in that most of the species present an erratic distribution (Alvariiño 1977, 1981; Sears 1953). Sears (1953:11) says: "There appears to be a tendency among coelenterates for a seemingly good species to appear in a particular locality, often in considerable numbers, and after a time to disappear, never to be seen again." This must be related to the peculiarity in patchiness and irregular aggregational distribution characteristics of siphonophores and other coelenterate populations, and the ineffectiveness of the plankton sampling gear in capturing these organisms (Biggs, Bidigare, and Smith 1981; Hamner et al. 1975). Because of their swimming behavior and speed, and their life cycle characteristics, siphonophores are capable of avoiding capture by plankton nets (Biggs 1977).

Acknowledgments

I would like to express my appreciation to Drs. Izadore Barrett, Frank Ferrari, John R. Hunter, and Reuben Lasker for reading the manuscript, and to Dr. Thomas E. Bowman and Ms. Martha Brown for their careful editing of the paper. My thanks are also due to Esperanza Manaligod for typing the table included in this work.
