Fortunes to be made on the deep slopes

The fishery resources of Pacific islands are often thought, even by people familiar with the Pacific, to consist only of the open ocean species such as tuna and billfish and the near-shore fishes and crustaceans found on shallow coral reefs.

However, on the deep slopes of the islands, there are fishery resources which are heavily exploited in only a few places, such as Hawaii. These resources represent an opportunity to expand island fisheries for small and medium sized multipurpose vessels.

The ex-vessel value of the fisheries for the deep slope resources in Hawaii for 1985 was conservatively estimated to be over $10 million.

The Southwest Fisheries Center Honolulu Laboratory, National Marine Fisheries Service (NMFS) has conducted research on deep slope resources in Hawaii and the Marianas.

One aspect of this work has been to estimate the maximum sustainable yields for a number of the deep slope resources. Many of the same deep slope fish and invertebrates occur throughout the Pacific.

The maximum sustainable fishery yields per area of appropriate habitat appear fairly constant among the Pacific islands. Thus the yields found in Hawaii and the Marianas can be used as first approximations for fishery development in other Pacific islands.

Perhaps the most common to all the islands are the bottom fish — jacks, snappers, and groupers found along the deep slopes at depths from 80 to 300 m. These fish usually weigh from 2 to 10 kg although some of the groupers can weigh over 100 kg.

The South Pacific Commission’s outer reef fishing program, together with NMFS survey work, has produced data for over 20 island archipelagoes. These show that most of the same species are found all across the Pacific but that the relative contribution of any species to the group at any island varies considerably.

In Hawaii the bottom fish resource is fished by recreational and commercial fishermen from vessels primarily in the 6 to 15 m range; hook-and-line gear operated with electric or hydraulic gurdies is used. These fish command a high price. In 1984, the average wholesale price was $5.83/kg, while the two highest priced species averaged $8.80 and $7.37/kg. However, these prices vary considerably with supply.

Based on our research in Hawaii and the Marianas we have found that it is useful to measure the habitat for these fishes at the length of the 100 fathom depth contour. We estimate that a yield of 250 kg of bottom fishes per nautical mile of 100 fm isobath appears to represent a reasonable supply.
Achipelago average for the maximum sustainable yield that can be expected from the bottom fish resource.

Thus an island chain with a length of 100 fm isobath of 500 nmi (about the size of the Marianas) can expect a maximum sustainable yield of 125 metric tons per year from its deep slope bottom fish fishery.

At a price of $5/kg this landing would be valued at $0.6 million. If the resource were fished by a fleet of 20 vessels the average landing per vessel would be 6.3 metric tons valued at $31,250.

Another deep slope resource which appears Pacific wide is deepwater shrimp. These are caught in baited traps in depths from 400 to 750 m. Although these shrimps (there are several related species) command a premium price (about $5.50/kg in Hawaii), the depth at which they are caught makes fishing for them an expensive proposition.

There have been several commercial ventures for these resources both in Hawaii and the Marianas but most have not proven successful. We estimate an archipelago average maximum sustainable yield of 200 kg of shrimp per square nautical mile of habitat.

Thus for an archipelago which has 1000 square nautical miles of habitat in the appropriate depth range (which is about the area of the deepwater shrimp habitat in the Marianas) the annual maximum sustainable yield for the deepwater shrimp resource is 200 metric tons. At a price of $5.50/kg the value of this landing would be $1.1 million.

Again, a fleet of 20 vessels harvesting this resource would have an average annual landing per vessel of 10 metric tons with a value of $55,000.

Although the value of these deep slope resources is very small in comparison to tuna, they are significant compared to the shallow water reef resources. Further they can be fished with small to medium sized vessels and can be marketed locally on most islands to hotels and restaurants.

The biggest concerns facing development of deep slope fisheries are overcapitalisation and overfishing. Initial catch rates in certain areas may be very high and when extrapolated over the habitat area of the archipelago may encourage large capital investment in the fishery.

However, these initial catch rates should not be taken to represent long term averages. Due to the limited habitat area it is easy to heavily fish the deep slope resources; to avoid the boom and bust cycle which often occurs in island fisheries it may be necessary to regulate the fishery. — Jeffrey Polovina.
